ECGs in Acute Myocardial Infarction Diagnosing an acute myocardial infarction by ECG is an important skill for healthcare professionals, mostly because of the stakes involved for the patient. One of the complications with using ECG for myocardial infarction diagnosis is that it is sometimes difficult to determine which changes are new and which are old.

The 12 lead ECG is used to classify MI patients into one of three groups: those with ST segment elevation or new bundle branch block (suspicious for acute injury and a possible candidate for acute reperfusion therapy with thrombolytics or primary PCI), those with ST segment depression or T wave inversion (suspicious for ischemia), and

Acute myocardial ischemia manifests on ECG as ST deviation (ST elevation or ST depression) and T-wave changes. ST deviation and T-wave changes are collectively referred to as ST-T changes. ST deviation indicates acute (ongoing) ischemia. In most cases ST deviations are accompanied by T-wave changes.

EKG: Acute Myocardial Infarction Patterns. An acute myocardial infarction (AMI) occurs due to the occlusion of a coronary artery with a thrombus formation. This event causes necrosis of cardiac tissue and can predispose the patient to the development of multiple dysrhythmias and death. The blood supply to the myocardium is accomplished through arteries that lie on the outside of the heart supplying the various areas of the myocardium.
